Abstract

The major goal of our paper is that we propose a platform, a design strategy, and evaluation criteria, for a fair and consistent hardware evaluation of FPGA. Then a low-cost and low power solution for this purpose should be sought. For portable and home entertainment audio systems, however the general DSP chip based solution might consume too much power. There exist two possible approaches that can reduce the chip area and power consumption. Hence this further reduces the power consumption. The Booth multiplication algorithm is implemented using Spartan3 FPGA from Xilinx, and it could also be implemented using Application specific Integrated Circuits (ASIC) when further One is the simplification of the FIR filter structure, and the other techniques include low power multiplier, adder, memory, supply voltage, etc. reduction in power consumption is required. The result shows that the proposed architecture is faster than the conventional CMOS architecture, along with reduced power consumption.

1, Introduction

In signal processing, a finite impulse response (FIR) filter is a filter whose impulse response (or response to any finite length input) is of finite duration, because it settles to zero in finite time. This is in contrast to infinite impulse response (IIR) filters, which may have internal feedback and may continue to respond indefinitely (usually decaying).

The impulse response of an Nth-order discrete-time FIR filter (i.e., with a Kronecker delta impulse input) lasts for $N + 1$ samples, and then settles to zero.

FIR filters can be discrete-time or continuous-time, and digital or analog.

Definition

A discrete-time FIR filter of order N . The top part is an N -stage delay line with $N + 1$ taps. Each unit delay is a z^{-1} operator in Z -transform notation.

where:

- $x[n]$ is the input signal,
- $y[n]$ is the output signal,
- b_i are the filter coefficients, also known as tap weights, that make up the impulse response,
- N is the filter order; an N th-order filter has $(N + 1)$ terms on the right-hand side. The $x[n - i]$ in these terms are commonly referred to as taps, based on the structure of a tapped delay line that in many,
- N is the filter order; an N th-order filter has $(N + 1)$ terms on the right-hand side. The $x[n - i]$ in these terms are commonly referred to as taps, based on the structure of a tapped delay line that in many implementations or block diagrams provides the delayed inputs to the multiplication operations. One may speak of a 5th order/6-tap filter, for instance.
- Require no feedback. This means that any rounding errors

are not compounded by summed iterations. The same relative error occurs in each calculation. This also makes implementation simpler. The main disadvantage of FIR filters is that considerably more computation power in a general purpose processor is required compared to an IIR filter with similar sharpness or selectivity, especially when low frequency (relative to the sample rate) cutoffs are needed. However many digital signal processors provide specialized hardware features to make FIR filters approximately as efficient as IIR for many applications.

The impulse response $h[n]$ can be calculated if we set $x[n] = \delta[n]$ in the above relation, where $\delta[n]$ is the Kronecker delta impulse. The impulse response for an FIR filter then becomes the set of coefficients b_n , as follows

Window Design Method

In the Window Design Method, one designs an ideal IIR filter, then applies a window function to it – in the time domain, multiplying the infinite impulse by the window function. This results in the frequency response of the IIR being convolved with the frequency response of the window function. If the ideal response is sufficiently simple, such as rectangular, the result of the convolution can be relatively easy to determine. In fact one usually specifies the desired result first and works backward to determine the appropriate window function parameter(s). Kaiser windows are particularly well-suited for this method because of their closed form specifications.

Moving average example

Fig. (a) Block diagram of a simple FIR filter (2nd-order/3-tap filter in this case, implementing a moving average)

study of computer architecture.

The Algorithm

Booth's algorithm examines adjacent pairs of bits of the N -bit multiplier Y in signed two's complement representation, including an implicit bit below the least significant bit, $y_{-1} = 0$. For each bit y_i , for i running from 0 to $N-1$, the bits y_i and y_{i-1} are considered. Where these two bits are equal, the product accumulator P remains unchanged. Where $y_i = 0$ and $y_{i-1} = 1$, the multiplicand times 2^i is added to P ; and where $y_i = 1$ and $y_{i-1} = 0$, the multiplicand times 2^i is subtracted from P . The final value of P is the signed product.

Consider a positive multiplier consisting of a block of 1s surrounded by 0s. For example, 00111110. The product is given by :

$$M \times "00111110" = M \times (2^5 + 2^4 + 2^3 + 2^2 + 2^1) = M \times 62$$

where M is the multiplicand. The number of operations can be reduced to two by rewriting the same as

$$M \times "010000-10" = M \times (2^6 - 2^1) = M \times 62.$$

In fact, it can be shown that any sequence of 1's in a binary number can be broken into the difference of two binary numbers:

$$(\dots \overbrace{01\dots 10}^n \dots)_2 \equiv (\dots \overbrace{10\dots 00}^n \dots)_2 - (\dots \overbrace{00\dots 10}^n \dots)_2.$$

Hence, we can actually replace the multiplication by the string of ones in the original number by simpler operations, adding the multiplier, shifting the partial product thus formed by appropriate places, and then finally subtracting the multiplier. It is making use of the fact that we do not have to do anything but shift while we are dealing with 0s in a binary multiplier, and is similar to using the mathematical property that $99 = 100 - 1$ while multiplying by 99.

This scheme can be extended to any number of blocks of 1s in a multiplier (including the case of single 1 in a block). Thus,

$$M \times "00111010" = M \times (2^5 + 2^4 + 2^3 + 2^1) = M \times 58$$

$$M \times "0100-11-10" = M \times (2^6 - 2^3 + 2^2 - 2^1) = M \times 58.$$

Booth's algorithm follows this scheme by performing an addition when it encounters the first digit of a block of ones (0 1) and a subtraction when it encounters the end of the block (1 0). This works for a negative multiplier as well. When the ones in a multiplier are grouped into long blocks, Booth's algorithm performs fewer additions and subtractions than the normal multiplication algorithm.

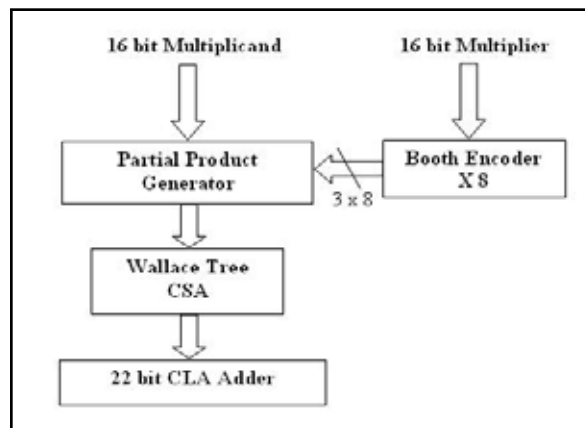

The representation of the multiplicand and product are not specified; typically, these are both also in two's complement representation, like the multiplier, but any number system that supports addition and subtraction will work as well. As stated here, the order of the steps is not determined. Typically, it proceeds from LSB to MSB, starting at $i = 0$; the multiplication by 2^i is then typically replaced by incremental shifting of the P accumulator to the right between steps; low bits can be shifted out, and subsequent additions and subtractions can then be done just on the highest N bits of P . There are many variations and optimizations on these details.

The algorithm is often described as converting strings of 1's in the multiplier to a high-order +1 and a low-order -1 at the ends of the string. When a string runs through the MSB, there is no high-order +1, and the net effect is interpretation as a negative of the appropriate value.

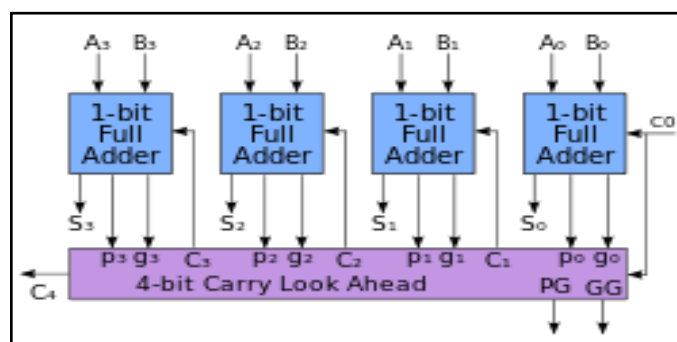

B. Proposed Technique

Hence, we can actually replace the multiplication by the string of ones in the original number by simpler operations, adding the multiplier, shifting the partial product thus formed by appropriate places, and then finally subtracting the multiplier. It is making use of the fact that we do not have to do anything but shift while we are dealing with 0s in a binary multiplier, and is similar to using the mathematical property that $99 = 100 - 1$ while multiplying by 99.

however; the general-DSP-chip-based solution might be too costly and consume too much power: Then a low-cost and low power solution for this purpose should be sought. By carefully examining digital audio processing applications, we believe

Carry-lookahead adder

4-bit adder with carry lookahead

A **carry-lookahead adder (CLA)** is a type of adder used in digital logic. A carry-lookahead adder improves speed by reducing the amount of time required to determine carry bits. It can be contrasted with the simpler, but usually slower, *ripple carry adder* for which the carry bit is calculated alongside the sum bit, and each bit must wait until the previous carry has been calculated to begin calculating its own result and carry bits. The carry-lookahead adder calculates one or more carry bits before the sum, which reduces the wait time to calculate the result of the larger value bits. The Kogge-Stone adder and Brent-Kung adder are examples of this type of adder.

Charles Babbage recognized the performance penalty imposed by ripple carry and developed mechanisms for *anticipating carriage* in his computing engines. Gerald Rosenberger of IBM filed for a patent on a modern binary carry-lookahead adder in 1957.

Theory of operation

A ripple-carry adder works in the same way as pencil-and-paper methods of addition. Starting at the rightmost (least significant)

digit position, the two corresponding digits are added and a result obtained. It is also possible that there may be a carry out of this digit position (for example, in pencil-and-paper methods, “9+5=4, carry 1”). Accordingly all digit positions other than the rightmost need to take into account the possibility

of having to add an extra 1, from a carry that has come in from the next position to the right.

This means that no digit position can have an absolutely final value until it has been established whether or not a carry is coming in from the right. Moreover, if the sum without a carry is 9 (in pencil-and-paper methods) or 1 (in binary arithmetic), it is not even possible to tell whether or not a given digit position is going to pass on a carry to the position on its left. At worst, when a whole sequence of sums comes to ...99999999... (in decimal) or ...11111111... (in binary), nothing can be deduced at all until the value of the carry coming in from the right is known, and that carry is then propagated to the left, one step at a time, as each digit position evaluated “9+1=0, carry 1” or “1+1=0, carry 1”. It is the “rippling” of the carry from right to left that gives a ripple-carry adder its name, and its slowness. When adding 32-bit integers, for instance, allowance has to be made for the possibility that a carry could have to ripple through every one of the 32 one-bit adders.

Carry lookahead depends on two things:

1. Calculating, for each digit position, whether that position is going to propagate a carry if one comes in from the right.
2. Combining these calculated values to be able to deduce quickly whether, for each group of digits, that group is going to propagate a carry that comes in from the right.

Supposing that groups of 4 digits are chosen. Then the sequence of events goes something like this:

1. All 1-bit adders calculate their results. Simultaneously, the lookahead units perform their calculations.
2. Suppose that a carry arises in a particular group. Within at most 3 gate delays, that carry will emerge at the left-hand end of the group and start propagating through the group to its left.
3. If that carry is going to propagate all the way through the next group, the lookahead unit will already have deduced this. Accordingly, *before the carry emerges from the next group* the lookahead unit is immediately (within 1 gate delay) able to tell the *next* group to the left that it is going to receive a carry - and, at the same time, to tell the next lookahead unit to the left that a carry is on its way.

The net effect is that the carries start by propagating slowly through each 4-bit group, just as in a ripple-carry system, but then move 4 times as fast, leaping from one lookahead carry unit to the next. Finally, within each group that receives a carry, the carry propagates slowly within the digits in that group.

The more bits in a group, the more complex the lookahead carry logic becomes, and the more time is spent on the “slow roads” in each group rather than on the “fast road” between the groups (provided by the lookahead

Again, the group sizes to be chosen depend on the exact details of how fast signals propagate within logic gates and from one logic gate to another.

For very large numbers (hundreds or even thousands of bits) lookahead carry logic does not become any more complex, because more layers of supergroups and supersupergroups can be added as necessary. The increase in the number of gates is also moderate: if all the group sizes are 4, one would end up with one third as many lookahead carry units as there are adders. However, the

“slow roads” on the way to the faster levels begin to impose a drag on the whole system (for instance, a 256-bit adder could have up to 24 gate delays in its carry processing), and the mere physical transmission of signals from one end of a long number to the other begins to be a problem. At these sizes carry-save adders are preferable, since they spend no time on carry propagation at all. sizes carry-save adders are preferable, since they spend no time on carry propagation at all.

Carry look ahead method

Carry lookahead logic uses the concepts of generating and propagating carries. Although in the context of a carry lookahead adder, it is most natural to think of generating and propagating in the context of binary addition, the concepts can be used more generally than this. In the descriptions below, the word digit can be replaced by bit when referring to binary addition.

The addition of two 1-digit inputs A and B is said to *generate* if the addition will always carry, regardless of whether there is an input carry (equivalently, regardless of whether any less significant digits in the sum carry). For example, in the decimal addition $52 + 67$, the addition of the tens digits 5 and 6 *generates* because the result carries to the hundreds digit regardless of whether the ones digit carries (in the example, the ones digit does not carry ($2+7=9$)).

In the case of binary addition, $A + B$ generates if and only if

both A and B are 1. If we write $G(A, B)$ to represent the binary predicate that is true if and only if $A + B$ generates, we have:

$$G(A, B) = A \cdot B$$

The addition of two 1-digit inputs A and B is said to *propagate* if the addition will carry whenever there is an input carry (equivalently, when the next less significant digit in the sum carries). For example, in the decimal addition $37 + 62$, the addition of the tens digits 3 and 6 *propagate* because the result would carry to the hundreds digit *if* the ones were to carry (which in this example, it does not). Note that propagate and generate are defined with respect to a single digit of addition and do not depend on any other digits in the sum.

In the case of binary addition, $A + B$ propagates if and only if at least one of A or B is 1. If we write $P(A, B)$ to represent the binary predicate that is true if and only if $A + B$ propagates, we have:

$$P(A, B) = A + B$$

Sometimes a slightly different definition of *propagate* is used. By this definition $A + B$ is said to propagate if the addition will carry whenever there is an input carry, but will not carry if there is no input carry. It turns out that the way in which generate and propagate bits are used by the carry lookahead logic, it doesn't matter which definition is used. In the case of binary addition, this definition is expressed by:

Given these concepts of generate and propagate, when will a digit of addition carry? It will carry precisely when either the addition generates *or* the next less significant bit carries and the addition propagates. Written in boolean algebra, with C_i the carry bit of digit i , and P_i and G_i the propagate and generate bits of digit i respectively,

The addition of two 1-digit inputs A and B is said to *propagate* if the addition will carry whenever there is an input carry (equivalently, when the next

Implementation Details

For each bit in a binary sequence to be added, the Carry Look Ahead Logic will determine whether that bit pair will generate a carry or propagate a carry. This allows the circuit to “pre-process” the two numbers being added to determine the carry ahead of time. Then, when the actual addition is performed, there is no delay from waiting for the ripple carry effect (or time it takes for the carry from the first Full Adder to be passed down to the last Full Adder). Below is a simple 4-bit generalized Carry Look Ahead circuit that combines with the 4-bit Ripple Carry Adder we used above with some slight adjustments:

6 *propagate* because the result would carry to the hundreds digit *if* the ones were to carry (which in this example, it does not). Note that propagate and generate Putting 4 4-bit CLAs together yields four group propagates and four group generates.

To determine whether a bit pair will generate a carry, the following logic works:

$$G_i = A_i \cdot B_i$$

To determine whether a bit pair will propagate a carry, either of the following logic statements work:

$$P_i = A_i \oplus B_i$$

$$P_i = A_i + B_i$$

The reason why this works is based on evaluation of

$$C_1 = G_0 + P_0 \cdot C_0$$

The only difference in the truth tables between $(A \oplus B)$ and $(A + B)$ is when both A and B are 1.

However, if both A and B are 1, then the G_0 term is 1 (since its equation is $A \cdot B$), and the $P_0 \cdot C_0$ term becomes irrelevant. The XOR is used normally within a basic full adder circuit; the OR is an alternate option (for a carry lookahead only) which is far simpler in transistor-count terms.

The Carry Look Ahead 4-bit adder can also be used in a higher-level circuit by having each CLA Logic circuit produce a propagate and generate signal to a higher-level CLA Logic circuit.

Manchester carry chain

The Manchester carry chain is a variation of the carry-look ahead adder that uses shared logic to lower the transistor count. As can be seen above in the implementation section, the logic for generating each carry contains all of the logic used to generate the previous carries. Dynamic logic can support shared logic, as can transmission gate logic. One of the major downsides of the Manchester carry chain is that the capacitive load of all of these outputs, together with the resistance of the transistors causes the propagation delay to increase much more quickly than a regular carry lookahead. A Manchester-carry-chain section generally won't exceed 4 bits.

III. Conclusion

For a complete hardware evaluation, there are plenty of evaluation platforms to be considered. Therefore, fixing one is crucial for conducting a fair and a consistent comparison. In this paper, propose an evaluation platform and a consistent evaluation

method to conduct a fair hardware evaluation of the remaining SHA-3 candidates. Using this method, we implement all the second-round SHA-3 candidates and obtain the resulting cost and performance factors. This technical study provides a fair and a consistent evaluation scheme. At the end, we hope that by sharing our experience we contribute to the SHA-3 competition and by providing the proposed methodology we influence other similar future selections of the standard cryptographic algorithms
